Model Reduction for Inverters with Current Limiting and Dispatchable Virtual Oscillator Control

Olaoluwapo Ajala, Member, IEEE, Minghui Lu, Member, IEEE, Brian Johnson, Member, IEEE, Sairaj Dhople, Member, IEEE, and Alejandro Domínguez-García, Senior Member, IEEE

Abstract—This paper outlines reduced-order models for grid-forming virtual-oscillator-controlled inverters with nested current- and voltage-control loops, and current-limiting action for over-current protection. While a variety of model-reduction methods have been proposed to tame complexity in inverter models, previous efforts have not included the impact of current-reference limiting. In addition to acknowledging the current-limiting action, the reduced-order models we outline are tailored to networks with resistive and inductive interconnecting lines. Our analytical approach is centered on a smooth function approximation for the current-reference limiter, participation factor analysis to identify slow- and fast-varying states, and singular perturbation to systematically eliminate the fast states. Computational benefits and accuracy of the reduced-order models are benchmarked via numerical simulations that compare them to higher-order averaged and switched models.

I. INTRODUCTION

The increasing deployment of inverter-based resources has altered the dynamic characteristics of electric grids. In this context, there has been significant attention, in recent years, on replacing synchronous power generators with grid-forming (GFM) inverter-based counterparts which, in the absence of synchronous generators, can sustain system voltages and frequency [1], [2]. Examples of such GFM control strategies include droop [3]–[5], virtual synchronous machines [6]–[10], and virtual oscillator control (VOC) [11]–[25].

Motivated by the fact that the VOC strategy is a globally stabilizing control strategy that is able to deal with higher-order harmonics [26], this paper leverages the theory of singular perturbation [27] to outline reduced-order models for a recently proposed variant of VOC called dispatchable virtual oscillator control (dVOC). The controller leverages the nonlinear dynamics of the Andronov-Hopf oscillator (AHO) to facilitate synchronization in low-inertia settings, and it also features functionality to respond to power and voltage setpoints [16]–[25]. A schematic representation of the three-phase GFM inverter we examine is sketched in Fig. 1. The constituent subsystems in the model include: i) the dVOC module that generates voltage and frequency setpoints; ii) an LCL filter; iii) a proportional-integral current controller with a current-reference limiter; and iv) a proportional-integral voltage controller that includes integrator anti-windup control.1 Two challenges immediately surface when considering the prospect of leveraging such models for system-level analysis. First, such models have multiple dynamic states (12 in this particular instance) which presents significant challenges to modeling dynamics of large networks of such inverters with limited computational burden. Second, the nonlinear elements sprinkled throughout the models (stemming from reference-frame transformations, current-reference limits, nonlinear GFM control strategies) present a non-trivial analytical impediment. Notably, these challenges hold true for a broad class of GFM inverter control methods going beyond the dVOC implementation we focus on.

Our main contribution is the development of reduced-order models for the dVOC flavor of GFM inverters that systematically acknowledge all pertinent nonlinearities in the model, particularly, the impact of the current-reference limiter. The current-reference limiter is a key element in the overall control scheme for GFM inverters since it addresses over-currents that would appear otherwise during faults and voltage sags [28]–[30]. It is typically realized with saturation functions that are incompatible with analytical approaches for model reduction. We circumvent this challenge with a smooth-function approximation that carries through the analytical developments. While reduced-order models have been proposed for GFM inverters (we review prior art shortly), to the best of our knowledge, these do not acknowledge current-reference limiters.

A majority of related literature in model reduction for GFM inverters is centered on droop control [31]–[35]. This is understandable since droop control is one of the earliest proposed GFM control strategies. There are recent efforts—albeit significantly fewer—focused on model reduction for other GFM controls, including virtual synchronous machines [36] and VOC [37]. These prior efforts have not considered the impact of the current-reference limiter in deriving reduced-order models. This singular aspect underscores the main contribution of our effort. Furthermore, we utilize participation-factor analysis to tease out distinct reduced-order models for dominantly resistive and dominantly inductive interconnecting lines. Such a systematic classification is particularly relevant, since it is well recognized that line attributes have non-trivial impact on system dynamics in low-inertia settings [18].

The remainder of this paper is organized as follows. Preliminaries are discussed in Section II, the full-order model is overviewed in Section III, and reduced-order models are derived in Section IV. Numerical results comparing the reduced-order models with full-order averaged and switched models are presented in Section V, and concluding remarks are given in Section VI.
II. PRELIMINARIES

A. Reference-frame Transformations & Notation

Consider the three-phase signal $f_{abc} = \{f_a, f_b, f_c\}^T$, where $f_a$, $f_b$, and $f_c$ form a balanced three-phase set. Let $\omega_b$ and $\omega(t)$ denote the nominal angular frequency and the GFM inverter’s angular frequency, in rad/s, respectively, and define

$$\theta(t) = \int_0^t \omega(\tau)\,d\tau + \theta(0), \quad \delta(t) = \theta(t) - \omega_b t.$$ (1)

Let $f_{DQ} = [f_D \ f_Q]^T$ and $f_{dq} = [f_d \ f_q]^T$ denote transformations of $f_{abc}$ to reference frames rotating at angular frequencies $\omega_b$ and $\omega(t)$, respectively. We define the $DQ$ and $dq$ transformations of $f_{abc}$ as follows:

$$f_{DQ} = T_1(\omega_b t)f_{abc}, \quad f_{dq} = T_1(\theta)f_{abc},$$ (2)

where transformation matrix $T_1(\cdot)$ is defined as:

$$T_1(\alpha) = \begin{bmatrix} \cos \alpha & \cos(\alpha - \frac{2\pi}{3}) & \cos(\alpha + \frac{2\pi}{3}) \\ -\sin \alpha & -\sin(\alpha - \frac{2\pi}{3}) & -\sin(\alpha + \frac{2\pi}{3}) \end{bmatrix}. \quad (3)$$

Signals in the $DQ$ and $dq$ reference frames are related via

$$f_{dq} = T_2(\delta)f_{DQ},$$ (4)

where rotation matrix $T_2(\cdot)$ is defined as

$$T_2(\alpha) = \begin{bmatrix} \cos \alpha & \sin \alpha \\ -\sin \alpha & \cos \alpha \end{bmatrix}. \quad (5)$$

The $2 \times 2$ identity matrix is denoted by $I$; $e_1 = [1, 0]^T$ and $e_2 = [0, 1]^T$ are the standard basis vectors.

B. Participation Factors

For the linear system $\dot{x} = Ax$, where $A \in \mathbb{R}^{n \times n}$, $x \in \mathbb{R}^n$, let $r_{ij}$ and $l_{ij}$ denote the $i$-th entries of the right and left eigenvectors associated with the $j$-th eigenvalue of $A$, respectively. The participation of the $i$-th element of $x$ in the $j$-th eigenvalue of $A$ is quantified by

$$\frac{|r_{ij}| l_{ij}|}{\sum_{i=1}^n |r_{ij}| l_{ij}|},$$ (6)

and is called the participation factor [38]. Hereafter, participation factors are normalized using their maximum values.

III. AVERAGED FULL-ORDER GFM INVERTER MODEL

In this section, we present the averaged full-order dynamical model for GFM inverters covering all control- and physical-layer subsystems. In subsequent developments, we use per-unit normalization (see, e.g., [39]) with the rated three-phase power, $S_r$, rated line-to-line voltage (RMS), $E_r$, and nominal system frequency, $\omega_b$, serving as base quantities for power, voltage, and frequency, respectively. This facilitates a unified and systematically normalized transcription of all parameters and variables in the dynamic models.

Table I summarizes numerical per-unit values for all the controller and filter parameters adopted in this work, with respective expressions for their base quantities enumerated. Controller and filter parameters are designed assuming $S_r = 1500$ VA, $E_r = 208$ V, $\omega_b = 2\pi \times 60$ rad/s, and a switching frequency of $10$ kHz. We discuss the design choices of pertinent parameters alongside the overview of each subsystem.

A. The Dispatchable Virtual Oscillator Controller

Let $P$ and $Q$ denote the active- and reactive-power delivered to the grid at the filter-capacitance terminals, and define $S = [P, Q]^T$. Furthermore, let $E^*, P^*$, and $Q^*$ denote references for the voltage magnitude, active power, and reactive power, respectively, and define $S^* = [P^*, Q^*]^T$. Following from the definitions of $\theta$ and $\omega$ in Section II-A, the dynamics of frequency and voltage-magnitude references are

$$\dot{\theta} = \omega = \omega_b + \frac{\omega_b \kappa_1}{(E^*)^2} T_2(\psi - \frac{\pi}{2})(S^* - S), \quad (7a)$$

$$\dot{E^*} = \frac{\omega_b \kappa_1}{E^*} e_2^T T_2(\psi - \frac{\pi}{2})(S^* - S) + \omega_b \kappa_2 (E_b^2 - (E^*)^2) E^*, \quad (7b)$$

where $E_b$ denotes the nominal inverter voltage magnitude, $\kappa_1$ is the synchronization gain, and $\kappa_2$ is the voltage-amplitude...
control gain. Furthermore, $\psi \in [0, 2\pi)$ denotes the rotation angle of the controller, which is typically tuned based on the Nyquist ratio of interconnecting lines. For instance, $\psi = \frac{\pi}{4}$ is well suited for inductive transmission lines since it yields active power-frequency and reactive power-voltage drop in steady state [16]. The model (7a)-(7b) is built from cycle-averaged dynamics of the Andronov-Hopf oscillator in polar coordinates.

Rationale for choice of $\kappa_1$, $\kappa_2$, and $\psi$: Numerical values for $\kappa_1$ and $\kappa_2$ listed in Table I ensure that the output voltage and frequency are approximately 0.95 pu and 59.5 Hz, respectively, when $S = [1, 1]^T$ (full load) and $S^* = [0, 0]^T$. In this context, the output voltage and frequency will return to their nominal values when we set $S^* = [1, 1]^T$ (see [16], [25] for details). The choice of rotation angle $\psi = \frac{\pi}{4}$ ensures a level of generality by preserving cross-coupling between active power, reactive power, frequency, and voltage.

The dynamical model for the unforced Andronov-Hopf oscillator in polar coordinates takes the general form: $\dot{r} = r(1 - r^2), \theta = \omega_0 t$. Suitably tailoring this to acknowledge inputs, leveraging periodic-averaging theory, and including pertinent scaling factors, yields (7a)-(7b).

### Conclusion

**B. The LCL Filter**

Let $U_{dq}$, $E_{dq}$, and $V_{DQ}$ denote the filter’s inverter-side, capacitor, and grid-side voltages, respectively. Let $I_{idq}$ and $I_{gdq}$ denote the filter’s inverter-side and grid-side currents, respectively. The filter dynamics are captured by

\[
\dot{I}_{idq} = \left(\omega T_2 \left(\frac{\pi}{2}\right) - \omega \frac{R_i}{L_i}\right)I_{idq} + \frac{\omega_b}{L_i} (U_{dq} - E_{dq}),
\]

\[
\dot{E}_{dq} = \omega T_2 \left(\frac{\pi}{2}\right) E_{dq} + \frac{\omega_b}{C} (I_{idq} - I_{gdq}),
\]

\[
\dot{I}_{gdq} = \left(\omega T_2 \left(\frac{\pi}{2}\right) - \omega \frac{R_g}{L_g}\right)I_{gdq} + \frac{\omega_b}{L_g} (E_{dq} - T_2(\delta) V_{DQ}),
\]

where $L_i$, $L_g$, and $C$ denote the inverter-side inductance, grid-side inductance, and capacitance of the LCL filter, respectively; $R_i$ and $R_g$ denote the non-ideal series resistances associated with the inverter- and grid-side inductors, respectively.

**Rationale for choice of $L_g$, $L_i$, and $C$:** One well-established approach for designing the LCL filter involves selecting a resonant frequency that is between ten times the value of the grid frequency (60 Hz in this case) and half the value of the switching frequency (10 kHz in this case) [40]. For a given resonant frequency (1.8 kHz in our design), picking the inverter-side inductance to be equal to the grid-side inductance ensures the smallest capacitive reactive power [41]. These design considerations yield the choice of values for $L_g$, $L_i$, and $C$ reported in Table I. The parasitic resistances follow from the hardware prototype realization discussed in [16].

**Remark 1 (Defining Active- and Reactive-power Outputs):** With the filter currents and voltages formally annotated, the active- and reactive-power outputs measured at the filter capacitors can be expressed as:

\[
P = E_{dq}^T I_{gdq}, \quad Q = E_{dq}^T T_2 \left(-\frac{\pi}{2}\right) I_{gdq}.
\]

**C. The Current-reference Limiter**

As depicted in Fig. 1, the current controller acts on a reference command, denoted by $I^{*}_{idq}$, which is generated by the voltage controller (to be described in detail later). As a first step, the magnitude of this reference is saturated to the inverter peak-current limit, $I_{max}$. In the literature, this has been accomplished with the following saturation function [19], [42]:

\[
\min \left(1, \frac{I_{max}}{||I_{idq}||_2}\right) I^{*}_{idq}.
\]

For analytical convenience, we model the current-reference limiting operation via the product $\rho I^{*}_{idq}$, where $\rho$ is given by:

\[
\rho = -\varepsilon \ln \left(\exp \left(-\frac{1}{\varepsilon}\right) + \exp \left(-\frac{I_{max}}{\varepsilon ||I_{idq}||_2}\right)\right).
\]

The $\min(\cdot, \cdot)$ function in (10) can be approximated by $\rho$ for small values of the saturation-function parameter, $\varepsilon$.

**Rationale for choice of $I_{max}$ and $\varepsilon$:** The choice of $I_{max}$ in Table I follows [42], which has espoused limits in this range for GFM inverters. The choice of $\varepsilon$ ensures a close match of the approximation $\rho$ to the $\min(\cdot, \cdot)$ function. (See Fig. 2.)
D. The Voltage Controller

The voltage controller acts on the terminal-voltage reference, denoted by \( E^* \), which is generated by the dVOC module and yields the current-control reference command, \( I_{\text{idg}}^* \). Let \( \Phi_{\text{idg}} \) denote the state variable of the voltage controller. The dynamics of the voltage controller are governed by

\[
\dot{\Phi}_{\text{idg}} = \omega_1(E^* - E_{\text{idg}}) + \omega_1K_{\text{b}}(\rho - 1)I_{\text{idg}},
\]

\[
\hat{\rho}I_{\text{idg}} = \frac{K_p}{\omega_b}\dot{\Phi}_{\text{idg}} + K_{\text{b}}\Phi_{\text{idg}} + I_{\text{gdq}} - \frac{\omega}{\omega_b}CT_2(\frac{\pi}{2})E_{\text{dq}},
\]

where \( \hat{\rho} = 1 + K_{\text{p}}/K_{\text{b}}(\rho - 1) \), \( K_{\text{p}} \) and \( K_{\text{b}} \), denote the voltage controller’s proportional and integrator gains, respectively, and \( K_{\text{b}} \), denotes the integrator anti-windup gain. In effect, (12a) and (12b) constitute a proportional-integral (PI) control system with reference \( E^* \), controlled signal \( E_{\text{idg}} \), and control input \( I_{\text{idg}}^* \). The loop includes a feed-forward compensation term, \( I_{\text{gdq}} - \frac{\omega}{\omega_b}CT_2(\frac{\pi}{2})E_{\text{dq}} \), and an integrator anti-windup term \( K_{\text{b}}(\rho - 1)I_{\text{idg}}^* \) [42], [43].

Rationale for choice of \( K_{\text{p}} \), \( K_{\text{b}} \), and \( \rho \). The bandwidth of the current-control loop (which we denote by \( \omega_{\text{bw,c}} \)) is typically one-tenth to one-fifth of the switching frequency, and that of the voltage-control loop (which we denote by \( \omega_{\text{bw,v}} \)) is multiple times slower for time-scale separation. The PI gains for the controller are set as \( K_{\text{p}}/\omega_b \approx 1 \) and \( K_{\text{b}} = 2K_{\text{p}}/\omega_{\text{bw,v}}/\omega_{\text{bw,c}} \) to yield an approximately first-order response [43]. A manual trial-and-error process is used to tune the value of \( K_{\text{b}} \).

E. Current Controller

Let \( \Gamma_{\text{idg}} \) denote the state variable corresponding to the current controller, and \( U_{\text{idg}}^* \) denote the output of the current controller. Note that \( U_{\text{idg}}^* \) generates the PWM reference signals for the inverter. The dynamics of the current controller are

\[
\dot{\Gamma}_{\text{idg}} = \omega_1(\rho^*_{\text{idg}} - I_{\text{idg}}),
\]

\[
U_{\text{idg}}^* = \frac{K_{\text{p}}}{\omega_b}\Gamma_{\text{idg}} + K_{\text{ii}}\Gamma_{\text{idg}} + E_{\text{dq}} - \frac{\omega}{\omega_b}L_1T_2(\frac{\pi}{2})I_{\text{idg}}^* + \hat{\rho}I_{\text{idg}} + K_{\text{b}}\Phi_{\text{idg}},
\]

where \( K_{\text{p}} \) and \( K_{\text{ii}} \) are the current-controller proportional and integrator gains, respectively. In effect, (13a)–(13b) close the loop around the inverter-side inductor current, \( I_{\text{idg}} \), with a PI loop that acts on a saturated version of the current reference, \( \rho^*_{\text{idg}} \). The feed-forward compensation term, \( E_{\text{dq}} - \frac{\omega}{\omega_b}L_1T_2(\frac{\pi}{2})I_{\text{idg}}^* \), in (13b) enhances disturbance rejection [43].

Rationale for choice of \( K_{\text{p}} \) and \( K_{\text{ii}} \). The PI gains are set as \( K_{\text{p}} = \omega_{\text{bw,l}}/L_i \) and \( K_{\text{ii}} = \omega_{\text{bw,l}}/R_i \) to yield an approximately first-order response from reference to output [43].

F. The Three-phase Inverter

The three-phase line-neutral voltage at the inverter switch terminals is captured by \( U_{\text{abc}} = \frac{V_{\text{dc}}}{3}m_{\text{abc}} \), where \( m_{\text{abc}} \) denotes the pulse-width modulation (PWM) signals and \( V_{\text{dc}} \) is the per-unitized dc-side voltage (see [43], pp. 115–126 for details). With the control architecture sketched in Fig. 1, it emerges that the averaged voltages at the inverter switched terminals in the \( dq \) reference frame are given by:

\[ U_{\text{dq}} = U_{\text{dq}}^* \]

IV. The Per-unit Reduced-order Models

In this section, we present the main results of this work, namely: reduced-order models for GFM inverters with dVOC acknowledging the current-reference limiter. The reduced-order models are sketched in Figs. 3a and 3b, for inverters with inductive and resistive interconnecting lines, respectively. Compared to Fig. 1, in both cases, the dynamics of the current- and voltage-control loops are abstracted, as are the dynamics corresponding to the inverter-side inductance, \( L_i \), and filter capacitance, \( C \). The impact of the current-reference limiter is preserved through an algebraic constraint in both cases.

We begin with a discussion on how to determine the dimension of the reduced-order models. Subsequently, we discuss the derivation of the reduced-order models and consider the special case without the current-reference limiter.

A. Determining the Order of the Reduced-order Models

The first step in model-order reduction is to identify fast and slow states in the inverter dynamical model while acknowledging that the inverter could be interconnected to a network with dominantly inductive or resistive lines. To aid this, in Fig. 4, we plot eigenvalues and participation factors corresponding to a linearized version of the inverter dynamical model for parameters presented in Table I and inputs: \( S^* = [2, 2]^T \) pu, \( V_{\text{DQ}} = [1, 0]^T \) pu. Two sets of results are plotted for inductive and resistive interconnecting lines, and they are distinguished based on the values of \( R_g \) and \( L_g \) utilized in the simulation. For the case with inductive (resistive) lines, we set \( L_g \) equal to the sum of the grid-side inductance (resistance) and the line inductance (resistance).

A careful examination of Fig. 4 reveals that a bandwidth of (approximately) 260 rad s\(^{-1}\) is a reasonable cut-off to separate slow and fast states for both inductive and resistive interconnections. The region shaded in gray in Fig. 4 identifies eigenvalues whose real parts take values less than \(-260 \) rad s\(^{-1}\), and should be considered as fast dynamics. The choice of the cut-off bandwidth is determined based on the locus of (the real-part of) eigenvalues most influenced by fast states that are not as strongly dependent on the nature of interconnecting lines. A careful examination of Fig. 4 suggests that in this case, these fast states are \( \Gamma_{\text{idg}} \), i.e., the states associated with the current controller. The inferences reported above hold for a wide range of inputs \( (S^*, V_{\text{DQ}}) \) and line parameters \( (R_g, L_g) \).

3The real-part of eigenvalues most impacted by \( \Gamma_{\text{idg}} \), emphasized in Fig. 4(d), is \(-266.7 \) rad s\(^{-1}\) for both cases considered. We establish the cut-off frequency to be 260 rad s\(^{-1}\) to go with a well-rounded number.
Fig. 3: Reduced-order models for GFM inverters with a current-reference limiter and dVOC.

Fig. 4: Eigenvalues of the averaged full-order model’s Jacobian matrix, with each eigenvalue color coded according to the participation factor of: (a) \( \delta = \theta - \omega_b t \), (b) \( E^* \), (c) \( I_{gdq} \), (d) \( \Gamma_{dq} \), (e) \( \Phi_{dq} \), (f) \( I_{idq} \), and (g) \( E_{dq} \). Elements of each \( dq \) variable have identical participation factors. The case of inductive (resistive) interconnecting lines is colored green (red). The region shaded in gray identifies eigenvalues associated with fast states.

B. Procedure Involved in Model-order Reduction

The results presented in this subsection are based on singular perturbation analysis [27]. We require the following reasonable assumption for the results to hold:

**Assumption 1.** The GFM inverter’s angular frequency, \( \omega \), satisfies the constraint

\[
\frac{\omega - \omega_b}{\omega_b} \leq \epsilon,
\]

where \( \epsilon \) is a dimensionless parameter.

For a nominal frequency, \( \omega_b = 60 \text{ Hz} \), and with the choice \( \epsilon = 260^{-1} \) (motivated by the discussion on cut-off bandwidth in Section IV-A), the above assumption implies that the reduced-order models that follow are valid when the GFM inverter’s frequency is within 59.77 Hz and 60.23 Hz.

The following steps are involved in model reduction:

1. The dynamics introduced in Section III are represented compactly as a 12th-order set of differential equations by
appropriate substituting algebraic equations.

2. The right- and left-hand sides of the differential equations for fast states are multiplied by \( \epsilon = 260^{-1} \). Resulting equations are in the standard singular perturbation form:

\[
\begin{aligned}
\dot{x} &= f(x, z, \epsilon), \\
\epsilon \dot{z} &= g(x, z, \epsilon),
\end{aligned}
\]

where \( f(\cdot, \cdot, \cdot) \) and \( g(\cdot, \cdot, \cdot) \) are continuously differentiable functions of their arguments, the elements of \( x \) are the slow-varying states, and the elements of \( z \) are the fast-varying states. From the discussion in Section IV-A, we note that when inductive lines interconnect the GFIM to the bus, \( x = [\theta, E^*, I_{idq}^T]^T \) and \( z = [I_{idq}^T, E_{dq}^T, \Phi_{idq}, I_{dq}^T]^T \).

When resistive interconnecting lines are used, \( x = [\theta, E^*]^T \) and \( z = [I_{idq}^T, I_{idq}^T, E_{dq}^T, \Phi_{idq}, I_{dq}^T]^T \).

3. The set of differential equations comprising (14b) are replaced with algebraic counterparts. We employ a zero-order approximation of the integral manifold for \( z \) as the algebraic counterpart; this is derived by setting \( \epsilon = 0 \) on the left-hand side of (14b), setting \( \omega_{\text{ref}} = 0 \) in the resulting set of equations (this follows from Assumption 1), and solving for \( z \) as a function of \( x \). The resulting set of equations yield a 4th-(2nd-) order model for GFIM inverters with inductive (resistive) lines.

C. Reduced-order Models

Following the steps above, it emerges that the action of the current-reference limiter is captured by solving for \( \rho \) in

\[
0 = \rho + \epsilon \ln \left( \exp \left( -\frac{1}{\epsilon} \right) + \exp \left( -\frac{I_{\text{max}} \sqrt{\frac{C^2 K_1^2 (\rho - 1)^2 + \rho^2}}}{\epsilon \| C e_2 E^* + I_{idq} \|^2_2} \right) \right) 
\]

(15)

Compared to (11), the above algebraic constraint is recognizably cumbersome; however, it captures the impact of current-reference limiting in an analytically tractable fashion.

We summarize the differential and algebraic equations corresponding to the two sets of reduced-order models next. Before doing so, we will find the below definitions useful:

\[
\begin{align*}
T_i(\rho) &= \begin{bmatrix}
\frac{\rho}{d(\rho)} - \frac{C K_1 (\rho - 1)^2}{d(\rho)} & 0 \\
\frac{C K_1 (\rho - 1)^2}{d(\rho)} & \frac{\rho}{d(\rho)}
\end{bmatrix}, \\
T_v(\rho) &= \begin{bmatrix}
0 & \frac{C^2 K_2 (\rho - 1)^2}{d(\rho)} \\
\frac{C^2 K_2 (\rho - 1)^2}{d(\rho)} & 0
\end{bmatrix}, \\
T_{iv}(\rho) &= \begin{bmatrix}
\frac{(C L_{idq} - 1) K_{iv} (\rho - 1) + R_{idq}^2}{\rho} & 0 \\
\frac{C R_{idq} K_{iv} (\rho - 1) - L_{idq}^2}{d(\rho)} & 0
\end{bmatrix}, \\
T_{gv}(\rho) &= \begin{bmatrix}
K_{iv} (\rho - 1) - R_{idq} d(\rho), & \frac{n_g(\rho)}{d(\rho)} \\
\frac{n_g(\rho)}{d(\rho)} & K_{iv} (\rho - 1) - R_{idq} d(\rho)
\end{bmatrix},
\end{align*}
\]

(16)

where, we introduce:

\[
d(\rho) = C^2 K_2^2 (\rho - 1)^2 + \rho^2,
\]

\[
n_g(\rho) = L_g^2 \rho^2 + C K_2^2 (\rho - 1)^2 (C L_{idq} - 1),
\]

\[
d_1(\rho) = (C L_{idq} - 1)^2 K_2^2 (\rho - 1)^2 + (C R_{idq}^2 K_2^2 (\rho - 1)^2
\]

\[
- 2 K_{iv} R_{idq} (\rho - 1) + \rho^2 (L_g^2 + L_{idq}^2).
\]

1) Inductive Interconnecting Lines: The dynamics of the slow-varying states are given by

\[
\dot{\theta} = \omega_b + \frac{\omega_b K_1}{E^*} T_2 (\psi - \frac{\pi}{2}) (S^* - S), \\
\dot{E} = \frac{\omega_b K_1}{E^*} e_2^T T_2 (\psi - \frac{\pi}{2}) (S^* - S) + \omega_b K_2 (E^* - (E^*)^2) E^*, \\
\dot{I}_{idq} = \omega_b (T_2 (\psi) (1 - \frac{1}{L_g C} (1 - \rho T_i(\rho))) - \frac{R_i}{L_g} I_{idq}), \\
+ \omega_b \left( \frac{\rho}{C} T_2 (\psi) T_i(\rho) e_1 E^* - T_2(\delta) V_{DQ} \right),
\]

(17)

where \( \rho \) is given by the solution of (15) and the active- and reactive-power values, \( P, Q \) in \( S = [P, Q]^T \) take the form:

\[
P = I_{idq}^T \left( \frac{\rho}{C} T_i(\rho) (T_2 (\psi) - \frac{1}{C} T_2 (\frac{\pi}{2})^T) \right) I_{idq}, \\
+ \frac{\rho}{C} T_2 (\psi) T_i(\rho) E^* I_{idq}, \\
Q = I_{idq}^T \left( \frac{1}{C} I - \frac{\rho}{C} T_i(\rho) \right) I_{idq}
\]

(18)

Algebraic equations for the fast-varying state variables are:

\[
I_{idq} = \rho T_i(\rho) e_1 E^* + T_i(\rho) I_{idq}, \\
E_{dq} = \frac{1}{C} T_2 (\psi) (I_{dq} - I_{idq}), \\
\Phi_{dq} = \frac{1}{\rho K_{iv}} (\rho - 1) (K_{iv} K_{pv} - 1) I_{idq}, \\
\Gamma_{dq} = \frac{R_{iv}}{K_{iv}} I_{idq}.
\]

(19)

2) Resistive Interconnecting Lines: The dynamics of \( \theta, E^* \) are the same as in (17a)–(17b); \( P, Q \) in \( S = [P, Q]^T \) remain defined as in (18a)–(18b); and \( \rho \) is still defined by the solution of (15). However, \( I_{idq} \), which is now a fast-varying state, is defined algebraically via

\[
I_{idq} = T_{iv}(\rho) e_1 E^* + T_{gv}(\rho) T_2(\delta) V_{DQ}.
\]

(20)

The algebraic equations for the other fast-varying state variables are the same as (19a)–(19d).

Remark 2 (Structure of Reduced-order Models). The reduced-order models for the slow-varying states in both cases considered above are self contained, in that they do not invoke any fast-varying states. The dynamics are DAE models in each case, with the algebraic component given by (15).

D. Special Case with Current-reference Limiter Ignored

The current-reference limiter can be ignored in the dynamical model presented in Section IV-B by setting \( \rho = 1 \). The collection of slow and fast states for the inductive and resistive interconnecting lines remains the same as before.

For inductive interconnecting lines, the dynamics of \( \theta \) and \( E^* \) are the same as (7a)–(7b), except, with the active- and
The algebraic equations for the fast-varying state variables are:

\[
\dot{I}_{dq} = C e_q E^* + I_{gdq}, \quad E_{dq} = e_1 E^*,
\]

\[
\Phi_{dq} = [0, 0]^T, \quad \Gamma_{dq} = \frac{R_i}{K_{fi}} (C e_q E^* + I_{gdq}).
\]

From above, we see that the filter-capacitor voltage, \(E_{dq}\), is regulated to the reference generated by the AHO model, \(e_1 E^*\).

For resistive interconnecting lines, the dynamics of \(\theta, E^*\) are the same as reported above for inductive interconnecting lines, as are algebraic constraints for \(I_{dq}, E_{dq}, \Phi_{dq}, \Gamma_{dq}\). The algebraic constraint for \(I_{gdq}\) can be recovered from (20) by substituting \(T_{in}(1)\) and \(T_{kv}(1)\).

V. NUMERICAL RESULTS

We consider a GFM inverter with dVOC interconnected to an infinite bus via: i) an inductive line, and ii) a resistive line. The active- and reactive-power references, and infinite-bus voltage are varied over a line. The active- and reactive-power references, and infinite-bus voltage are regulated to the reference generated by the AHO model, \(e_1 E^*\).

VI. CONCLUDING REMARKS & FUTURE WORK

This work outlined reduced-order models for grid-forming inverters realized with dispatchable Virtual Oscillator Control. Compared to previous efforts for model reduction, our proposed models retain the effects of the current-reference limiter in the model response. Simulation results indicate that the proposed reduced-order models require an order-of-magnitude less computational effort to produce results with the same order-of-magnitude accuracy as the averaged full-order model. Future work includes extending the results presented in this paper to other types of GFM inverters.
